

Activity Engagement Summary

Synthetic evidence attachment | Four observation sessions | No personal identifiers

Pattern

Attention declined most often after 20 minutes in repetitive seated activities. Engagement was more stable during familiar music, paired conversation, and short movement breaks. Early departure was recorded in three of four worksheet sessions and in none of the music sessions.

Concern boundary

The pattern raises a participation and social-connection concern. It should not be described as cognitive decline without repeated person-level observations, baseline information, and alternative explanations such as fatigue, hearing access, session timing, or activity design.

Evidence gap

The source records do not consistently capture session duration, room noise, hearing-device use, individual baseline attention, or whether a format change improved participation.

Recommended verification

Compare participation duration across activity types for two weeks. Record the first sign of disengagement, the context, any accommodation offered, and the response after the activity changes.

Prepared only for end-to-end product testing.
